Exosomes as Potent Cell-Free Peptide-Based Vaccine. II. Exosomes in CpG Adjuvants Efficiently Prime Naive Tc1 Lymphocytes Leading to Tumor Rejection

Nathalie Chaput,* Noël E. C. Schartz,** Fabrice André,* Julien Taïeb,* Sophie Novault,* Pierre Bonnaventure,* Nathalie Aubert,† Jacky Bernard,‡ François Lemonnier,¶ Miriam Merad,§ Gosse Adema,# Malcolm Adams,¶¶ Maria Ferrantini,|| Antoine F. Carpentier,‡‡ Bernard Escudier,* Thomas Tursz,* Eric Angevin,‡ and Laurence Zitvogel²,³*

Ideal vaccines should be stable, safe, molecularly defined, and out-of-shelf reagents efficient at triggering effector and memory Ag-specific T cell-based immune responses. Dendritic cell-derived exosomes could be considered as novel peptide-based vaccines because exosomes harbor a discrete set of proteins, bear functional MHC class I and II molecules that can be loaded with synthetic peptides of choice, and are stable reagents that were safely used in pioneering phase I studies. However, we showed in part I that exosomes are efficient to promote primary MHC class I-restricted effector CD8⁺ T cell responses only when transferred onto mature DC in vivo. In this work, we bring evidence that among the clinically available reagents, Toll-like receptor 3 and 9 ligands are elective adjuvants capable of triggering efficient MHC-restricted CD8⁺ T cell responses when combined to exosomes. Exosome immunogenicity across species allowed to verify the efficacy of good manufactory procedures—manufactured human exosomes admixed with CpG oligonucleotides in prophylactic and therapeutic settings of melanoma in HLA-A2 transgenic mice. CpG adjuvants appear to be ideal adjuvants for exosome-based cancer vaccines. The Journal of Immunology, 2004, 172: 2137–2146.

Spinning molecular immunology into successful immunotherapy to amplify immune responses and break Ag-specific tolerance has been and remains an important challenge to date. The rational design of vaccines initially involves identification of the immune effector mechanisms responsible for protection against disease (cellular immune responses for cancer) and the subsequent selection of an Ag capable of eliciting the desired adaptive response. A productive immune response is defined by the generation of clonally expanded Ag-specific T (or B) cells, requiring effective Ag presentation to specific TCR on naive T cells (or membrane-bound Ig on B cells). In some cases, in addition to this signal 1, a delivery signal 2 of costimulatory molecules or cytokines is provided by APCs and requested for the priming of CD4⁺ T cells, helper arms of CTL effectors (or Ag-specific B cells) (1–3). Adjuvants (adjuvare is Latin for “to help”) serve as critical components in the design of effective, nonreplicating vaccines to enhance or boost immunogenicity of coadministered Ags (4). Molecular definition of adjuvants has been surrounded by obscurity and called the “immunologist’s dirty little secret” by Janeway (6) in 1989 (2, 5, 6). Attempts have been made to classify adjuvants functionally according to at least five concepts of immunogenicity: first, the geographical concept of immunogenicity (1), and second, the theory of depot effect (7), both emphasizing the importance of Ag localization for a period of time after immunization; third, the paradigm that adjuvants act as signal 0, i.e., trigger signaling of pattern recognition receptors and activation of innate immune cells to release cytokines/chemokines (8, 9); fourth, the hypothesis that adjuvants induce or act as danger molecules (stressed or damaged tissues alerting APCs to up-regulate costimulatory molecules) (10, 11); and finally, the role of signal 2 through cytokines and costimulation as natural adjuvants (6, 12, 13).

Dendritic cells (DC) are likely to play a central role as nature’s adjuvants because of their unique ability to turn on naive T cells at a mature stage of differentiation (14, 15). The maturation or activation of DC occurs in response to a broad array of signals, either pathogen-associated molecular pattern molecules (through Toll-like receptors (TLRs)), or endogenously produced signals of the TNF family members (through TNFR or CD40 ligand) (16–19).

Abbreviations used in this paper: DC, dendritic cell; BM-DC, bone marrow-derived DC; Ex, DC-derived exosome; iDC, immature DC; LN, lymph node; mDC, mature DC; ODN, oligonucleotide; TLR, Toll-like receptor; Tc1, effector T lymphocytes secreting INF-γ.
Upon maturation, they become capable of activating innate effector cells (NK and NK cells) (20, 21), and move from the periphery to the draining lymph nodes (LN) via afferent lymphatics (22). Immunostimulation by adjuvants may result from increased attraction of DC toward the injection site (23), increased loading (or cross-presentation) of exogenous Ag by MHC class I molecules of APCs (24), or increased transport of Ag-loaded APCs toward the LN (25, 26). Hence, DC represent ideal targets for vaccine adjuvants, and cytokine-DC interactions are indispensable for linking innate and cognate immunity (27).

We described exosomes as membrane vesicles originating from DC late endosomes and secreted constitutively in vitro upon fusion of multivesicular membrane with plasma membrane (28, 29). In the first part (58), we brought evidence that: 1) DC produce exosome-associated MHC class I complexes that are functional for CTL priming; 2) exosomes require mature DC (mDC) for T cell activation in vitro and in vivo; and 3) exosomes exhibit comparable efficacy as mDC to initiate synthetic peptide-specific CD8+ T cell responses in vivo. Therefore, the design of an efficient exosome-based cancer vaccine requires an adjuvant that should mimic or substitute for mDC in vivo. In this second part, we show that: 1) exosome-mediated CD8+ T cell priming can be triggered using CpG DNA oligomeric sequences (and dsRNA); 2) most of the clinically available alternative adjuvants that do not directly activate DC in vivo cannot boost exosome immunogenicity in the HHD2 mouse model; 3) in the B16 melanoma tumor model co-expressing human HLA-A2 and gp100 tumor Ag, 10^10 exosomal MHC class I molecules presenting gp100 peptides admixed with CpG oligonucleotides (ODN) mediate tumor rejection as efficiently as 3 x 10^9 mDC-A2/gp100 and more efficiently than high dosages of peptides stressing that exosomes are valuable cell-free peptide vaccines.

Materials and Methods

DC culture

Mouse bone marrow-derived DC (BM-DC) were cultured, as previously described (12). Briefly, bone marrow progenitor cells were grown in IMDM culture medium (Sigma-Aldrich, St. Quentin Fallavier, France), supplemented with 50 μM penicillin, 50 μg/ml streptomycin, 2 mM l-glutamine, 10% decomplemented FCS (Life Technologies, Paisley, U.K.), 50 μM 2-ME (Sigma-Aldrich), and 30% J558 murine GM-CSF culture supernatants for 10–12 days. At day 11, maturation of BM-DC was induced by adding LPS (5 μg/ml; Sigma-Aldrich) to culture medium for 24 h. For in vivo immunization protocols, BM-DC were used at day 12. The phenotype of BM-DC was analyzed by flow cytometry using anti-mouse CD11c, I-A^q, CD80, CD86, and CD40 mAb (BD PharMingen, Heidelberg, Germany), and H-2K^b and H-2D^b (22). In addition, BM-DC propagated from HHD2 mice were stained with MA2:1 Ab-ascitic fluids.

Exosome production and purification

Exosomes were either isolated using the classical process of a series of differential ultracentrifugation already described (11, 12) or isolated according to a process of ultracentrifugation/diafiltration derived from Lamparsky et al. (30). Briefly, 2–4 L of DC culture medium was microfritted (3 μm) and then ultrafiltered through a 500-kDa filter up to a final volume of 50 ml. This 50 ml of exosome-containing medium was supplemented with up to 1 L of PBS, and a second step of 500-kDa ultrafiltration was performed, leading to a final volume of 20–50 ml. This preparation was ultracentrifuged at 100,000 x g onto a D20/30% sucrose gradient-density cushion (d = 1.217). The exosomal pellet recovered in the cushion was dialyzed for sterilization and will be referred to as exosomes henceforth.

MHC class I immunocapture assays for exosomal MHC class I quantification

A titrated mouse anti-human MHC class I mAb (HLA- A, B, C, BD PharMingen) was incubated with excess exosomes that had dried in a 96-well plate and subsequently blocked with 6% nonfat milk. After a 1-h incubation, the plate was washed and incubated with addition of excess goat anti-mouse Ab (Jackson Immunoresearch Laboratories, West Grove, PA) conjugated to HRP for 1 h at room temperature. The plate was developed for 5 min using the ECL substrate system, as described by the manufacturer (Amersham Pharmacia, Uxbridge, France). Chemiluminescence signal was measured by the Wallac trilux chemiluminometer (PerkinElmer, Gaithersburg, MA).

Pulsing of exosomal MHC class I peptide complexes with Mart12635 peptides and gp100 peptides

To elute the endogenous MHC class I peptides bound to exosomes, 100 μl of exosomes (10^12 MHC class I molecules) is treated with an equal volume of acetate buffer, pH 5.1, containing the synthetic CTL epitope MelanA/Mart1/ELAGLCRTV at 10 μM at 4°C for 30 min (ExMart1). After such an acidification, the preparation is neutralized with a Tris buffer, pH 11, on ice for 15 min to allow reformation of the trimolecular MHC class I peptide complexes. Then unbound peptides and debris are removed using an ultracentrifugation (100,000 x g/min, 40 min) step on a D20/30% sucrose gradient-density cushion. The exosomes recovered in the cushion are subsequently ultracentrifuged (100,000 x g, 1 h). The pellet is resuspended in 1 x PBS and stored at -80°C. Unbound peptides cannot exceed a final concentration of 1–7 nM. The process is similar for gp100 154-162, HLA-A0201/mlu, and gp100 209–217/h-250/251.

MelanA/Mart1-specific CD8+ T cell induction in HHD2 mice

Human D6 (HHD2) mice derived from a strain deficient for mouse β2–microglobulin and H-2D^d molecules and transgenic for a chimeric MHC class I molecule, HLA-A0201/D6, linked to the human β2-microglobulin (24), were provided by F. Lemonnier (Pasteur Institute, Paris, France). Transgenic mice were immunized in the footpad with 50 μl of the vaccine. Different vaccine designs were used (DC-derived exosome (Ex) alone, Ex onto mDC, Ex in CpG, Ex in poly(I:C), mDC or immature DC (iDC)/peptides, CpG/peptides). Detailed experimental settings are described in figure legends. Briefly, mouse ExA2/Mart1 (ExK7) or mouse ExA2/gp100 (ExA2/mDC-GP100) exosomes were either inoculated directly intradermally or pulsed onto 3 x 10^7 H-2D^d mDC (DC(K7)) or HHD2 mDC (DC(A2)). Immunocapture assays with an internal standard allowed monitoring of the numbers of MHC class I molecules/exosome batch. Each group of three to five animals was immunized in the footpad with 4 x 10^7, 2 x 10^7, or 10^6 exosomal MHC class I molecules. Other vaccines consisted in direct injection of peptide-pulsed iDC or mDC HHD2 DC. A single dose of 3 x 10^6 DC was loaded with increasing concentrations (from 0.01 to 10 μM) of MelanA/Mart126–35 (ELA) peptides. Alternatively, various amounts of ExA2 154–162 pulsed with Mart126–35 were mixed with endotoxin-free CpG oligomeric sequences (5′-TCC ATG AGC TTC CTG AGC TT-3′) (30 μg of CpG/mouse in a total volume of 50 μl for footpad inoculation) or associated to i.v. administration of poly(I):poly(C) (poly(U)) dsRNA (Ampligen, 2.5 mg/ml; Biocline, Republic of South Africa; provided by M. Adams, Velindre Hospital, Cardiff, U.K.); type I IFN, produced by M.F., as previously described (27, 28). Dendrotoxin-derived muramidase derived from muramyl dipeptide kindly provided by G. Bahar, Laboratoire d’Immunologie Moléculaire de l’Infection et de l’Inflammation, Institut Pasteur de Lille and ISTAC Biotechnologie (Lille, France) (32), and Montanide (ISA 720; SEPPIC, Paris, France). Each experimental group contained three to five mice, and experiments were performed at least three times. Pooled data of the most representative experiments are shown on the graphs. Mice were immunized once on day 0, and popliteal and inguinal draining LN and controlateral nodal were harvested on day 5. LN mononuclear cells were first stained with A2/Mart1 or A2/HIV gag fluorescent (PE) soluble tetramers (0.2 μg) for 30 min at room temperature in 20 μl of 1× PBS/0.5% BSA (Sigma-Aldrich), then with anti-CD3 FITC mAb and anti-CD8 allophycocyanin mAb (BD PharMingen) for 30 min at room temperature before washing steps and analysis in a FACS-Calibur (BD Biosciences, Heidelberg, Germany). We set up the significant values based on: 1) the staining achieved with an irrelevant tetramer (A2/HIV on relevant nodes (25, 26), or 2) the staining achieved with the relevant tetramer (A2/Mart1 on controlateral or naive LN in control mice, as well as on LN-draining footpads inoculated with unpulsed exosomes. The mean ± SEM percentage of tetramer staining with A2/gag HIV on relevant nodes (n = 20) was 0.16 ± 0.13, representing absolute numbers of 437 ± 250 cells; the mean ± SEM percent-age of tetramer staining with A2/Mart1 on naive nodes (n = 20) was 0.35 ± 0.3, representing absolute numbers of 1750 ± 970 cells; the mean ± SEM percentage of tetramer staining with A2/Mart1 on LN-drain ing vaccination with unpulsed exosomes (n = 20) was 0.54 ± 0.4, representing absolute numbers of 1063 ± 970 cells. The cutoff value for significance at 5000 ± 1000 cells. Function of LN-residing
T cells following immunization was assessed by challenging LN mononuclear cells to grading doses of Mart1 peptides. Supernatants were collected at 48–72 h to evaluate IFN-γ, IL-4, and IL-10 levels in ELISA (BD PharMingen).

Tumor models

B16F10 ectransfected with the human HLA-A2 and gp100-encoding cDNA was kindly provided by the Department of Tumor Immunology, University Hospital Nijmegen (G.A.). A total of 3 × 10⁶ tumor cells was inoculated on day 0 in the right abdominal flank, and vaccine consisting of mature BM-DC or human HLA-A*0201 exosomes in CpG oligos (as precised above) at increasing dosage was administered twice on days 5 and 10 (V1 and V2) in the footpad, as mentioned in Fig. 4 legend, or days 3 and 14, as mentioned in Figs. 5 and 6. Peptide pulsing onto exosomes or mature BM-DC was performed using two gp100 peptides (gp100 154–162\textsubscript{i}T\textsubscript{W\textsubscript{G}O\textsubscript{V}Y\textsubscript{W}O\textsubscript{Y}V\textsubscript{i} and gp100 209–217\textsubscript{i}M\textsubscript{D\textsubscript{E}K\textsubscript{G}F\textsubscript{V}P\textsubscript{F}SV\textsubscript{i}) at 50 μg/ml. Tumor growth was monitored biweekly using a caliper.

Statistical analyses

Absolute numbers of CD8⁺ T cells and IFN-γ levels have been analyzed using an ANOVA with Fisher’s exact method. Significances within 95, 99, and 99.9% confidence interval are depicted on the graphs with *, **, and ***, respectively. Comparisons between groups were performed using the nonparametric Kruskal-Wallis test.

Results

CpG ODN substitute for nature’s adjuvants in exosome-mediated CTL priming

We first showed that exosomal MHC class I molecules require transfer onto mDC to promote efficient CTL priming in vivo (58). To facilitate the clinical implementation of exosomes, we looked for a synthetic adjuvant that would trigger DC maturation in vivo. Synthetic ODN that contain unmethylated CG dinucleotides in particular sequence contexts (CpG motifs) mimic bacterial DNA (33) and have been shown to boost innate immune responses and promote acquired Th1-biased cellular and humoral immunity (34, 35). In mice, CpG ODN directly target myeloid and plasmacytoid DC and trigger their activation (36–38). Therefore, we first analyzed the ability of CpG ODN to enhance exosome-mediated Mart1-specific CTL responses in HHD2 mice. Because we demonstrated that efficient MHC class I-restricted Ag presentation could be achieved using exosomes pulsed onto mDC (58), we aimed at comparing efficacy of effector T lymphocytes secreting IFN-γ (Tc1) differentiation using CpG vs mDC for priming with exosomes. Immunization with exosomes pulsed with Mart1\textsubscript{26–35} epitopes was performed between 10⁶ and 10⁷ MHC class I molecules in the presence of mDC (HHD2) or CpG oligomeric sequences (Fig. 1). As previously shown (58), exosomes loaded onto synegetic mDC(A2) significantly expanded ELA-specific CTL (Fig. 1A, p < 0.01) that differentiate into potent Tc1 (Fig. 1B, p < 0.01) with a plateau reached at 2 × 10⁶ MHC class I molecules (p > 0.05 between 2 × 10⁵ ExA2⁺/ELA and 1 × 10⁶ ExA2⁺/ELA, Fig. 1). Similar efficacy for both CTL expansion (5–7% tetramer-binding CD8⁺ T cells; Fig. 1 inset) and Tc1 differentiation (Fig. 1B) was achieved using ExA2⁺/ELA in CpG adjuvants with up to 1 × 10⁸ exosomal A2⁺/ELA molecules required for CTL responses (p < 0.05 compared with ExA2⁺; Fig. 1A). In all cases, IFN-γ secretion by LN-residing CD8⁺ T cells was peptide dependent (data not shown). There were no statistically significant differences between mDC and CpG ODN at 1 × 10⁵ exosomal A2⁺/ELA molecules to trigger Tc1 differentiation (Fig. 1, p > 0.05).

Exosomes are more effective CTL inducers than peptide-based vaccines in conjunction with CpG adjuvants

The capacity of exosomes to prime CD8⁺ naïve T cells was compared with that mediated by peptide alone, both in conjunction with CpG ODN. Bioactivity of CpG sequences was checked in vitro on iDCs. A total of 10–30 μg of CpG sequences triggered BM-DC maturation (data not shown), in contrast to mock sequences. Footpad immunization using free Mart1\textsubscript{26–35} peptides in the presence of CpG sequences was analyzed at grading ranges (0.01–20 μM) of peptides. Even at high peptide dosage, vaccination with Mart1 peptides adjuvantized in CpG (30 μg) weakly primed Mart1-specific CTL (p > 0.05; Fig. 1). It is noteworthy that while up to 20 μM of ELA peptides adjuvantized in CpG did not significantly promote Mart1-specific CTL expansion (Fig. 1A), ExA2⁺/ELA adjuvantized in CpG did (ExA2⁺/ELA-linked 10⁻¹⁰ MHC class I molecules, p < 0.01 compared with ExA2⁺; Fig. 1A). Moreover, such ExA2⁺/ELA adjuvantized in CpG elicited Mart1-specific Tc1 cells more efficiently than 20 μM of ELA adjuvantized in CpG (p < 0.05 between 1 × 10⁸ ExA2⁺/ELA and 20 μM of ELA; Fig. 1B).

However, peptide stability following intradermal injection is known to be poor. Therefore, immunogenicity of 2 × 10⁻¹⁰⁰ exosomal ExA2⁺/ELA complexes in CpG ODN was compared with that mediated by 3 × 10⁶ mDC(A2) pulsed with saturating concentrations of peptides in HHD2 mice. Indeed, in our model system, a plateau of Tc1 differentiation was achieved with mDC using ~0.3–0.5 × 10⁹/footpad injection (data not shown). The threshold for exosome efficacy in Tc1 priming was ~2 × 10⁵–1 × 10⁶ MHC class I molecules in CpG ODN. Importantly, there was no statistically significant difference between: 1) 10⁵ ExA2⁺/ELA in CpG ODN and mDC pulsed with 0.1–10 μM of Mart1 regarding the expansion of A2⁺ Mart1⁺ tetramer-binding CD8⁺ T cells (p > 0.05; Fig. 1A), and 2) 10⁶ ExA2⁺/ELA in CpG ODN and mDC pulsed with 1–10 μM of Mart1 regarding the priming of Mart1-specific Tc1 (p > 0.05; Fig. 1B).

CpG ODN could be considered appropriate adjuvants that enable Ex to be immunogenic vehicles of MHC class I/peptide complexes for the differentiation of Tc1 cells. Moreover, exosomes in CpG ODN could substitute for mDC in the initiation of synthetic peptide-specific primary CD8⁺ T cell responses.

Bioactivity of human GMP exosomes in mice

To test whether exosomes could be implemented in the setting of human cancer vaccines, we explored the capacity of human exosomes to mediate tumor rejection in mice. Therefore, we first address the cross-species bioactivity of exosomes by inoculating exosomes secreted from human HLA-A*0201 monocyte-derived DC in HHD2 mice. As shown in Fig. 2, human HLA-A*0201 exosomes pulsed with Mart1 peptides can elicit mouse CTL priming in HHD2 mice with significant expansion of CD8⁺ T cells binding the A2/Mart1 tetramers (Fig. 2A) and secreting ng levels of IFN-γ after short ex vivo stimulation with Mart1 peptides (Fig. 2B). Like mouse HHD2 exosomes, human HLA-A*0201 exosomes (at 10⁻¹⁰ ExA2⁺/ELA molecules) required synthetic adjuvants, i.e., bacterial DNA sequences (CpG) to efficiently prime CTLs. These data suggest that: 1) preclinical studies in mice can be performed using GMP human exosomes, and 2) a conserved molecular pattern of APC recognition by exosomes might be involved and activated by CpG ODN.

dsRNA are also capable of boosting exosome-mediated CTL primary responses

We tested clinically available adjuvants in conjunction with Ex (experimental designs listed in Fig. 3A). Some cytokines are known to be natural adjuvants (27). Montoya et al. (39) reported that murine DC secrete and respond to type I IFNs, identifying these cytokines as autocrine DC activators for the priming of naive
FIGURE 1. Figure legend continues
could not promote exosome-mediated Tc1 expansion or differentiation in HHD2 (Fig. 3, B and C). However, a significant recruitment of both plasmacytoid DC and B cells was achieved in draining LN on day 5 (data not shown) following inoculation of exosomes and type I IFNs.

Secretion of IL-2 by mouse DC is important in conferring to these cells a T cell-priming capacity that is severely impaired in DC isolated from IL-2−/− knockout mice (40). Moreover, IL-2 has been shown to promote specific and nonspecific T cell responses in humans (41). However, neither IL-2 s.c. nor IL-2 i.p. (100,000 IU each injection; Fig. 3A) could significantly induce exosome-mediated Tc1 differentiation in HHD2 (Fig. 3, B and C).

Murabutide is a safe (apyrogenic) synthetic immunomodulator derived from muramyl dipeptide, the minimal bioactive structure of the bacterial cell wall peptidoglycan (32). Murabutide has been shown to enhance nonspecific resistance to bacterial and viral infections (42). Murabutide has also been shown to synergize with cytokines such as IFN-α (43) and IL-2 (44). Because murabutide has been clinically evaluated and was found to modulate cytokine release without toxicity (45), we tested the association of exosomes along with murabutide (10 mg/kg) or the combination of murabutide and IFN-α or IL-2 (Fig. 3A). As shown in Fig. 3, B and C, none of these associations could promote significant expansion of Mart1-specific CD8+ T cells in draining LN.

Montanide (46) was also tested with no adjuvant capacity along with exosomes (data not shown), but the stability of the mixture has to be evaluated in details.

In contrast, the dsRNA poly(I):poly(C (47), has been evaluated in chronic fatigue syndrome and cancer (48, 49).

Altogether, mostly TLR3 and TLR9 ligands were significant inducers of CD8+ T cell priming along with Ex in vivo.

**Human exosomes in CpG adjuvants are suitable melanoma vaccines**

Because human exosomes maintain their immunogenicity across species (at least in rodents), we investigated the capacity of human exosomes to reject establishment of day 6 nonpalpable B16F10 melanoma cotransfected with human HLA-A2 and gp100 cDNA. As expected, mouse HHD2 mature BM-DC pulsed with both gp100 peptides (gp100154−162 and gp100209−217) were potent antitumor vaccines with up to 60% tumor-free mice achieved with 3 × 10^5 mature cells at saturating doses of peptides (Fig. 4A). It is noteworthy that above the therapeutic level of 3 × 10^5 mDC into the footpad, results were less impressive, presumably because of the limited area of vaccine inoculation. DC-mediated antitumor
effects were peptide specific (Fig. 4A). In a similar setting, HLA-
A*0201 human exosomes pulsed with both gp100 peptides and
admixed with CpG ODN were also efficient at preventing tumor
growth with up to 40% tumor-free animals at the end of the ex-
periments. Only the highest exosome dose level, i.e., \(10^8\) exosomal MHC class I molecules pulsed with gp100, was consistently
mediating significant antitumor effects, while \(2 \times 10^9\) or \(4 \times 10^8\)
could not (Fig. 4B). These antitumor effects were in part peptide
specific because CpG with \(10^{10}\) unpulsed exosomal MHC class I
molecules could not significantly prevent tumor growth (Fig. 4B).
In such a setting, human exosomes did not bear the appropriate
MHC class II molecules necessary to trigger CD4+ T cell help and
long-lasting CD8+ memory T cell responses, in contrast to
syngeneic mDC.

Another set of tumor experiments was performed to prevent the
growth of large s.c. tumors at the time of vaccine inoculation using
various peptide-based vaccine designs (mDC, exosomes, free peptides). Fig. 5 depicts the efficacy of $3 \times 10^5$ mature HHD2 DC pulsed with gp100 to abrogate spontaneous tumor growth in a peptide-specific manner. Although CpG ODN display no significant antitumor effects, the association of CpG ODN and exosomes (at $10^6$ ExA2/gp100) mediates significant growth retardation in HHD2 ($p < 0.05$; Fig. 5). It is noteworthy that unpulsed exosomes do exhibit modest antitumor effects, albeit not significant ($p > 0.05$; Fig. 5). As expected from data shown in Fig. 1 comparing free peptides vs exosomes in CpG ODN, exosomes were more efficient than high dosages of free peptides in hampering tumor growth of pre-established tumors (Fig. 6).

Discussion
Following our first report showing that Ex display abundant MHC class I/peptide complexes that require transfer onto mDC to become functionally active on specific TCRs (58), we addressed whether clinically available adjuvants causing DC maturation in vivo could substitute for ex vivo propagated mDC to allow exosome-mediated T cell priming in vivo. In this work, we show that

![Diagram](http://www.jimmunol.org/)
TLR3 and TLR9 ligands appear to be the most effective components in mice and that CpG ODN could be suitable exosome adjuvants not only for inducing Ag-specific CTL priming, but also for antitumor effects.

The TLR9 ligand, CpG ODN, appears to mirror part of the effects mediated by mDC when associated with exosomes. CpG ODN were reported to bring an infectious danger signal that acutely triggers innate nonself pattern recognition and to initiate immune responses (50). These responses are Th1 polarized (51, 52) and result in enhanced hemopoietic activity (53). Aseptic immunostimulation with CpG ODN induces in mice local lymphadenopathy associated with long-term local immune hypersensitivity, which promotes Tc1 CTL and Th1 responses to Ag and infection (52). CpG ODN predispose local draining LN to respond to Ags by dramatically augmenting the number of CD11c+ cells (20× at day 1; 300× at day 10) that produce IL-12 and possibly IFN-γ. These environmental queues lead to CTL activation, with concomitant up-regulation of IL-12Rβ2 and IFN-γ synthesis by T cells (52). CpG ODN activate in vivo peptide-presenting DC to trigger protective CTL antiviral responses (53). Up-regulation of MHC class II, CD40, CD80, and CD86 on DC cell surface was monitored in the draining LN of footpads injected with peptides admixed with CpG-ODN 1668 ~12–24 h after inoculation. Activation of Ag-presenting iDC can be brought up by CD40 ligand+ Th cells or by direct DC recognition of pathogen-derived ligands. Vabulas et al. (54) showed that CpG ODN allowed induction of Th cell-independent CTL responses toward MHC class I-restricted T cell epitopes. More recently, plasmacytoid DC have been identified as the primary targets of CpG ODN (36, 54, 55). However, the precise cellular target for exosomes resulting in the efficient presentation of MHC class I/peptide complexes to CTL in vivo is not yet known and is currently under investigation.

Despite their profound local effect in draining LN for the development of Ag-specific Tc1 differentiation, CpG ODN in association with irradiated tumor cells could not protect mice against subsequent tumor challenge. However, peritumoral CpG ODN elicited a coordinated response of CD8+ T cells and innate effectors leading to long-term, tumor-specific protection (56). In this study, we show that exosomes in association with CpG ODN, both injected at a distant site from inoculated tumors, induce significant antitumor effects in vivo in the aggressive B16F10 melanoma model. One could hypothesize that exosomes most likely target...

objective clinical responses will be reported. The demonstration that
unpublished data), although some ob-
could be detected in circulating blood of cancer patients immu-
nizing patients in the absence of other adjuvants than MHC class II
assumptions require further investigations.

It is interesting to note that our data support a better priming and therapeutic efficacy achieved using exosomes compared with free peptides in vivo (Figs. 1 and 6). This result could be accounted for by the better stability of exosomes in the dermo-epidermis and/or by the selective exosome targeting of APC capable of promoting efficient CTL responses and/or by additional intermediate effectors stimulated by exosomes that would facilitate CTL activation. Such assumptions require further investigations.

Our data provide a rationale for the use of TLR3 or TLR9 ligands as adjuvants for the implementation of Ex in the armamentarium of cancer vaccines. Two exosome-based phase I clinical trials are being conducted currently using Mage-A1/B35 and Mage-D/DP04 peptides in nonsmall cell lung and melanoma-bearing patients in the absence of other adjuvants than MHC class II epitopes. Preliminary data indicated that no CTL responses could be detected in circulating blood of cancer patients immunized with exosomes (our unpublished data), although some objective clinical responses will be reported. The demonstration that Ex are valuable vectors of MHC/peptide complexes in humans is still awaiting, but our data encourage to launch a second phase II clinical trial combining exosomes with efficient adjuvants.

Acknowledgments
We thank Dee wei Hsu for providing some materials and methods for exosomal GMP production, and S. Amigorena, G. Raposo, and C. Théry for critical review of the manuscript and fruitful discussions. We are indebted to Dominique Gamboa, Annick Duval, and Christian Loy from Etablissement Français du Sang Nord de France for assistance with the apheresis, and to P. Arduin and its animal facility for mice handling.
